Abstract

The banded organization of clouds and zonal winds in the atmospheres of the outer planets has long fascinated observers. Several recent studies in the theory and idealized modelling of geostrophic turbulence have suggested possible explanations for the emergence of such organized patterns, typically involving highly anisotropic exchanges of kinetic energy and vorticity within the dissipationless inertial ranges of turbulent flows dominated (at least at large scales) by ensembles of propagating Rossby waves. Here we present results from an attempt to reproduce such conditions in the laboratory. Achievement of a distinct inertial range turns out to require an experiment on the largest feasible scale. Deep, rotating convection on small horizontal scales was induced by gently and continuously spraying dense, salty water onto the free surface of the 13m diameter cylindrical tank on the Coriolis Platform in Grenoble, France. A ‘planetary vorticity gradient’ or ‘ β -effect’ was obtained by use of a conically-sloping bottom and the whole tank rotated at angular speeds up to 0.15 rad s^{-1} . Over a period of several hours, a highly barotropic, zonally-banded large-scale flow pattern was seen to emerge with up to 5-6 narrow, alternating, zonally-aligned jets across the tank, indicating the development of an anisotropic field of geostrophic turbulence. Using particle image velocimetry (PIV) techniques, zonal jets are shown to have arisen from non-linear interactions between barotropic eddies on a scale comparable to either a Rhines or ‘frictional’ wavelength which scales roughly as $(\beta/U_{\text{rms}})^{-1/2}$. This resulted in an anisotropic kinetic energy spectrum with a signif-

icantly steeper slope with wavenumber k for the zonal flow than for the non-zonal eddies, which largely follow the classical Kolmogorov $k^{-5/3}$ inertial range. Potential vorticity fields show evidence of Rossby wave breaking and the presence of a ‘hyper-staircase’ with radius, indicating instantaneous flows which are super-critical with respect to the Rayleigh-Kuo instability criterion and in a state of ‘barotropic adjustment’. The implications of these results are discussed in light of zonal jets observed in planetary atmospheres and, most recently, in the terrestrial oceans.

1. Introduction

The banded organization of clouds and zonal winds in the atmospheres of the outer planets has long fascinated atmosphere and ocean dynamicists and planetologists, especially with regard to the stability and persistence of these patterns. This banded organization, mainly apparent in clouds thought to be of ammonia and NH_4SH ice, is one of the most striking features of the atmosphere of Jupiter. The cloud bands are associated with multiple zonal jets of alternating sign with latitude (Limaye 1986; Simon 1999; García-Melendo and Sánchez-Lavega 2001; Porco et al. 2003), with zonal velocities in excess of 100 m s^{-1} and widths of order 10^4 km . Similar patterns of multiple zonal jets are also found in the atmospheres of Saturn (Sánchez-Lavega et al. 2000; Porco et al. 2005; Sánchez-Lavega et al. 2006) and the other gas giants, though on different absolute scales.

A similar pattern of zonation may also occur in the Earth’s oceans, though on a very different scale to those of the gas giant planets. Patterns of zonally banded flow are fairly ubiquitous in numerical model simulations of ocean circulation carried out with sufficient horizontal resolution. In practice this seems to require a resolution of at least $1/6^\circ$ in latitude and longitude,

within which banded flows appear on a scale of $2\text{-}4^\circ$ (Galperin et al. 2004; Maximenko et al. 2005; Richards et al. 2006) which are coherent in the east-west directions for 1000 km or more. Such features often appear to be surface-intensified, but extend coherently to great depths in an equivalent-barotropic form. The observational evidence for this phenomenon is still quite sketchy, however, though similar features are now becoming apparent in suitably filtered satellite altimeter data (Maximenko et al. 2005), at least in medium-long term time averages.

The dynamical origin of these banded structures remains poorly understood, although the fact that the jets decay with height in the upper tropospheres and lower stratospheres of Jupiter and Saturn would suggest that they are driven by momentum sources in the weakly-stratified region in the atmosphere below the visible clouds. The depth to which this pattern of winds penetrates below the clouds remains controversial, but most approaches towards understanding the processes organising the flow into zonal bands have suggested that the pattern may originate from the anisotropy in a shallow turbulent layer of fluid due to the β -effect, i.e., owing to the latitudinal variation of the effective planetary vorticity (e.g. see Ingersoll et al. (2004) and Vasavada and Showman (2005)).

Until recently, quantitative understanding of this process has been based principally on high resolution numerical simulations of two-dimensional or geostrophic turbulence in stirred rotating fluids (Williams 1978, 1979; Vallis and Maltrud 1993; Chekhlov et al. 1996; Galperin et al. 2001; Huang et al. 2001; Sukoriansky et al. 2002; Williams 2003; Galperin et al. 2006). This has led to the notional concept of a rotating fluid which is stirred on small scales and within which kinetic energy cascades to larger scales via nonlinear interactions. The formation of jet-like structures occurs through the effects of anisotropies introduced by the presence of a ‘planetary vorticity gradient’, because of which eddies of a large enough scale are constrained to propagate zonally in a dispersive manner reminiscent of Rossby waves. This results eventually in an accumulation of kinetic energy in zonally-elongated structures, ultimately in the form of zonal jets. The mechanism for scale selection of such jet-like structures, however, has remained somewhat obscure, although the scale separating jets which emerge in modelled flows often seems to be comparable with the so-called Rhines scale $L_R \simeq (U_{\text{rms}}/\beta)^{1/2}$ (Rhines 1975), where U_{rms} is a measure of the rms total horizontal velocity fluctuations and β is the ‘planetary vorticity gradient’ ($= (2\Omega \cos \phi)/a$ for a spherical planet, where Ω is the planetary rotation rate, a the planetary radius and ϕ is latitude). Others (e.g. Galperin et al. (2001), Sukoriansky et al. (2002)) have attributed at least part of the scale selection mechanism to the balance between upscale energy transfer and pro-

cesses removing energy at the largest scales. Under some circumstances (including systems dominated by Ekman bottom friction) this leads to a direct connection between the so-called ‘frictional’ wavenumber (at which frictional and dynamical timescales are roughly comparable) and the Rhines scale, though for other conditions the scale selection mechanism is less clear (e.g. see Sukoriansky et al. (2007)).

While such models can provide useful and interesting insights into possible mechanisms for banded flows, they are highly idealised and take little account of the vertical structure of realistic geophysical fluid systems. It is sometimes difficult, therefore, to relate results from such studies directly to geophysical problems. Laboratory experiments can provide an alternative means for studying these processes in a real fluid, for which approximations and assumptions underlying simplified models do not apply. In the present context, a β -effect can be emulated by use of conically-sloping topography, at least for quasi-barotropic flow (e.g. Read (2001)). However, previous investigations to date (Mason 1975; Condie and Rhines 1994; Bastin and Read 1998), have been unable to access regimes at a sufficiently high Reynolds number (or low enough Ekman number) to be able convincingly to demonstrate fully developed, non-linear zonation effects.

Here we report the results of new experiments, conducted on the world’s largest rotating platform, which seek to confirm that multiple zonal jets may indeed be generated and maintained by internal nonlinear zonation processes. Some preliminary results from this study were published by Read et al. (2004), in which some of the basic flow patterns were discussed and aspects of the anisotropic spectra presented for two of the main experimental cases investigated. In this paper, we present a more detailed analysis of the results of these experiments, considering not only the form of flow pattern which may develop in the presence of background rotation and sloping or flat bottom topography, but also the detailed interactions between different scales of motion in terms of energy and potential vorticity. Section 2 describes the experimental configuration and introduces the main analysis methods. Section 3 presents an overview of the main scales of motion and the range of phenomenology observed during the sequence of experiments. Sections 4 and 5 examine diagnoses first of the direct eddy-zonal flow interactions, and then the detailed 2D kinetic energy spectra and anisotropic transfers in Fourier space. Section 4 considers the observed structure of the flow in terms of potential vorticity dynamics and instabilities. The final section 7 discusses all of these results in the context of the geophysical and planetary systems introduced above.

2. Apparatus and data analysis

The experiments were performed on the 13 m diameter ‘‘Coriolis’’ rotating platform in Grenoble, France. The schematic layout of the configuration is illustrated in Fig. 1 and the values of the main parameters are listed in Table 1. The experiment consisted of a large circular cylindrical container of diameter 13.0 m and maximum depth $h = 1.5$ m, set coaxially on the turntable. An equivalent topographic β -effect was obtained by imposing a conical slope at the bottom of the circular container, such that the imposed ‘planetary vorticity gradient’, β was given by

$$\beta = \frac{2\Omega}{h} \frac{dh(r)}{dr}, \quad (1)$$

where r is the radial coordinate and Ω the rotation rate of the tank. The bottom slope was implemented by using a plastic-coated, fabric sheet, stretched between a circular tubular frame, set just inside the outer radius of the tank, and a circular jig close to the centre of the tank whose height could be adjusted via a clamp attached to a post on the axis. This sheet could also be removed relatively easily to enable additional experiments with a flat bottom, in order to compare the flow structure both with and without a topographic β -effect. The upper surface was free and open to the air. This meant that there was unavoidably a weak centrifugal deformation of the upper surface, even when the bottom surface was flat. At the highest rotation rate used, however, this led to a difference in height across the tank from the centre to the rim of only ~ 5 cm. The rotation period of the platform, τ_r , was set to $\tau_r = 40$ seconds for most experiments, though some additional experiments were carried out with a rotation period of $\tau_r = 80$ s. The working fluid was a homogeneous weak salt solution of mean density 1026 kg m^{-3} , within which small, neutrally-buoyant particles (of diameter 0.5 mm) could be suspended for flow visualization and measurement (see below).

2a. Convective forcing

A key objective of this study was to investigate the properties of geostrophic turbulence maintained by a mechanism which was as ‘natural’ and unconstrained as possible. In particular, it was considered important to apply forcing on a relatively small horizontal scale, but which was not fixed in position relative to the rotating reference frame.

To achieve this, convective forcing was applied by gently spraying relatively dense, salty water onto the main fluid layer from a reservoir located above the centre of the tank. A system of spray nozzles was set up along a radial arm, which could be rotated around the tank in either direction at a speed controlled independently of the rotation of the main tank. The spacing of the nozzles was carefully designed so that, as the arm

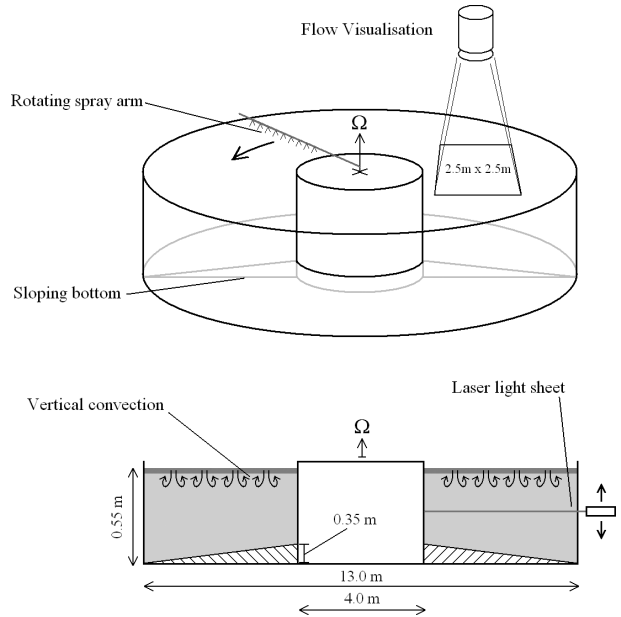

Figure 1: Schematic cross-section of the circular container, showing the rotating spray arm used to provide continuous convective forcing and the field of view of the narrow angle camera. The entire apparatus is set on a circular turntable.

was rotated, the flux of salty water deposited onto the free upper surface of the tank was as uniform as possible. In practice, tests indicated that the volume flux from this system was uniform across the entire radius of the tank to better than $\pm 10\%$. The flow speed and direction of each jet was set so as to disturb the surface of the water as little as possible. For most runs carried out, the spray arm was rotated with a period of 30-50 seconds in either the prograde or retrograde direction while depositing approximately $5\text{-}7 \text{ litres min}^{-1}$ of salty water.

By varying the density of the water spray a range of buoyancy fluxes $F_B = g(\Delta\rho/\rho)F_V$ (where g is the acceleration due to gravity, $\Delta\rho$ is the difference in density between the working fluid and spray, and F_V is the volume flux of the spray) could be obtained ranging from approximately $10^{-9} - 10^{-7} \text{ m}^2 \text{ s}^{-3}$. For most runs a buoyancy flux of around $F_B = 4.5 \times 10^{-8} \text{ m}^2 \text{ s}^{-3}$ was obtained. Together with a rotation rate of $(1 - 2)\pi/40 \text{ rad s}^{-1}$ and a depth h of around 30-40 cm, this would be expected to lead to a field of convection with a ‘natural Rossby number’, Ro^* Fernando et al. (1991); Maxworthy and Narimousa (1994); Marshall and Schott (1999), defined by

$$Ro^* = \left(\frac{F_B}{f^3 h^2} \right)^{1/2}, \quad (2)$$

(where $f = 2\Omega$) of around $1 - 3 \times 10^{-3}$. Such a value

would indicate a convective regime somewhat similar to that of deep convection in the terrestrial oceans Marshall and Schott (1999), and imply that rotation should exert a strong influence on the form of convection.

2b. Flow measurement

The horizontal velocity fields were obtained from plan view CCD images by a Correlation Imaging Velocimetry (CIV) method (Fincham and Spedding 1997; Fincham and Delerce 2000). Neutrally-buoyant tracer particles of diameter 0.5 mm were suspended in the flow and illuminated by a beam from a 6 W argon-ion laser located at the side of the tank and introduced through a glass panel in the outer wall. The beam was rapidly scanned in the horizontal to create a diverging light sheet across a chord through the annular channel, at a depth which could be selected by moving the laser on a computer-controlled carriage.

The illuminated tracer particles were observed from above at a height of approximately 4 m above the surface of the tank by two digital cameras, a low-resolution, wide-angle camera with resolution 768×484 and covering an area $4.5 \text{ m} \times 3.3 \text{ m}$, and a higher resolution, narrow-angle camera with a resolution of 1024×1024 and covering an area $2.5 \text{ m} \times 2.5 \text{ m}$. This allowed the observation of the largest feasible area of the tank, given the limited height of the building in which the rotating facility was accommodated, though represented a maximum of just 12% of the total surface area of the annular channel which was visible simultaneously. By aligning the long axis of the wide-angle camera with the radius of the tank however, the optimum coverage of the zonal flow profile across the tank could be obtained. This did mean that a true instantaneous zonal average could not be measured directly, though use of time-averaging would help to recover a more global sample of flow statistics.

Flow fields were obtained every 20s from groups of images obtained by each camera over time interval of up to 3s. By applying CIV analysis to these bursts of images, velocities could be measured to a precision of better than $\pm 0.1 \text{ mm s}^{-1}$ (relative to typical velocities of a few mm s^{-1}) on a 72×48 point (wide-angle) or 98×98 point (narrow-angle) rectangular grid. In order to diagnose the azimuthal anisotropy of the evolving flow, the velocity fields were subsequently decomposed into radial and zonal (*i.e.*, azimuthal) components and mapped into $(r, r\theta)$ coordinates, where r is the radius from the centre of the tank and θ the azimuthal angle (increasing anticlockwise from above; see Fig. 2(a)). For the purposes of presentation and analysis, we also make use of a simple local cartesian system with x in the (clockwise) θ direction (so $x = -r\theta$, usually measured from the radial centre line of the camera image) and r in the outwards radial direction.

In addition to long series of horizontal flow fields,

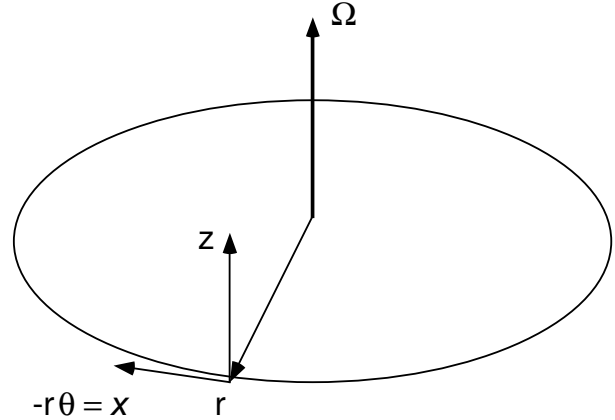

Figure 2: The coordinate systems used in this paper in relation to the cylindrical tank. For some purposes, the cylindrical coordinate system (r, θ, z) is used alternately with a local cartesian system (x, r, z) , for which $x = -r\theta$ is in the *clockwise* ($-\theta$) direction.

a few measurements were made of the flow in the azimuth-height $((r\theta, z)$ or $(-x, z)$) plane near mid-radius by re-orienting the laser light-sheet into a vertical plane and viewing with the wide-angle camera through a second glass panel in the outer wall. This enabled the flow over a $0.5 \text{ m} \times 0.5 \text{ m}$ area to be measured in order to examine the flow pattern forced directly by the overhead spray.

The vertical profile of density in the flow could be measured at intervals to an accuracy of approximately $\pm 1 \text{ kg m}^{-3}$ using a conductivity probe, mounted on the operator gantry at mid-radius and which could be driven downwards into flow from the surface to within 10 cm of the bottom of the tank on command via a motor-driven carriage.

3. Scales and Flow Morphology and Variability

In this section we describe the basic flow structures which were obtained over a range of conditions. Because of limited time available for this investigation, only a few combinations of parameters could be explored. Accordingly we concentrate on discussing a set of just three runs whose parameters are listed below in Table 1. A few additional short experiments were also carried out at other parameter settings (especially with varying buoyancy forcing), though with only limited flow measurements.

Table 1: Experimental parameters for the three main experiments covering the full range of β obtainable. τ_r is the rotation period of the turntable while τ_E is the mean Ekman spindown timescale $= h/\sqrt{\nu\Omega}$.

Run	τ_r (s)	Bottom slope ($^\circ$)	β ($\text{m}^{-1} \text{s}^{-1}$)	F_B ($\times 10^{-8} \text{ m}^2 \text{ s}^{-3}$)	U_{rms} (cm s^{-1})	τ_E (s)
I	40	0	0.004	4.6	0.20	1387
II	80	4.5	0.035	21.0	0.67	1962
III	40	4.5	0.08	4.5	0.34	883

3a. Vertical measurements

As discussed above, the forcing of the flow was effected by spraying dense, salty water onto the free surface of the tank from a rotating arm in the frame of the rotating table. This initially produced a shallow layer of dense fluid on the top surface of the flow which rapidly became statically unstable (on a timescale of a few seconds), leading to the formation of discrete plumes of salty water which would then descend towards the bottom of the tank. This is illustrated in Fig. 3, which shows two dye visualizations of descending plumes in the azimuth-height ($(r\theta, z)$ or $(-x, z)$) plane of the tank close to mid-radius for a case with a flat bottom, a rotation period of 80s and buoyancy flux of approximately $1.7 \times 10^{-7} \text{ m}^2 \text{ s}^{-3}$.

Fluorescein dye was introduced at the surface of the tank as the spray arm moved overhead above the field of view. This was then entrained into the plumes, which could be seen descending and spreading horizontally as they moved towards the bottom of the tank. It is noteworthy from such images (e.g. in Fig. 3(b)) that, although the convective mixing is initially most vigorous in the uppermost 25% of the depth of the tank (Fig. 3(a)), individual plumes actually reach the bottom of the tank, albeit with some azimuthal tilting, indicative of deep, penetrative convection.

The velocity field associated with these plumes was obtained via CIV analysis of sequences of these images, using the dispersion of neutrally-buoyant particles to trace the flow. A typical example of such a velocity field is shown in the (x, z) plane at mid-radius in Fig. 4.

The velocity field is evidently dominated by irregular, descending jets of fluid associated with each plume, on a horizontal scale of around 10 cm, again clearly traversing the entire depth of the tank along a sloping trajectory. The flow pattern appears to evolve rapidly, on timescales less than the rotation period of 80 s, thus representing a significantly ageostrophic, three-dimensional convective flow on these scales.

Although this convective flow would suggest the presence of a statically unstable stratification, in practice the conductivity probe always measured either a neutral or *weakly stable* density gradient. The vertical density gradient was typically found to evolve during the course of an experiment lasting a few hours, beginning with essentially neutral stratification and then gradually de-

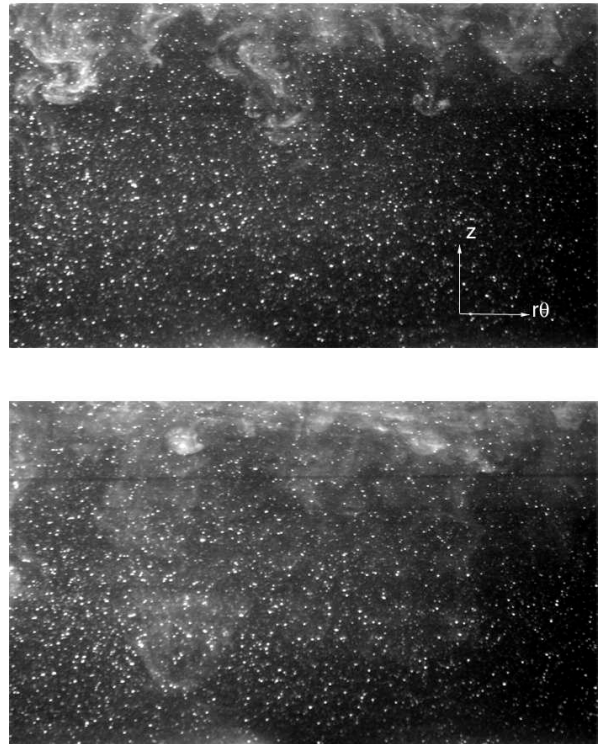

Figure 3: Two visualizations of convective plumes in the azimuth-height plane of the Coriolis tank, rotating with a period of 80 s and with a flat bottom and viewed from the side using a wide-angle digital camera. The field of view is approximately $0.74 \text{ m} \times 0.55 \text{ m}$ in $(r\theta, z)$, with the bottom of the tank approximately at $z = 0$, and plumes are visualized using fluorescein dye introduced at the top surface as the spray arm moves overhead across the field of view. The two images are separated by approximately 110 s (~ 1.5 rotation periods).

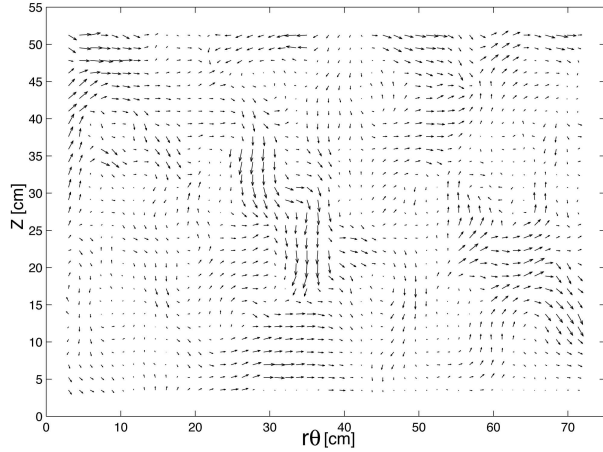

Figure 4: Flow field in the presence of convective plumes in the azimuth-height plane of the Coriolis tank, rotating with a period of 80 s and with a flat bottom and viewed from the side using a wide-angle digital camera. The maximum vector length corresponds to a velocity of approximately 10 mm s^{-1} .

veloping a weakly stable gradient in the lower part of the tank with a maximum value of $\partial\rho/\partial z$ of around $1\text{-}2 \text{ kg m}^{-4}$. The upper part of the tank remained approximately neutrally stratified with no clear evidence of unstable stratification, which was probably confined to a thin layer near the top surface, though this could not be measured reliably.

These measurements would suggest a crude estimate of an upper limit on N^2 of $\sim 5 \times 10^{-3} \text{ s}^{-2}$, where

$$N^2 = -\frac{g}{\rho_0} \frac{\partial\rho}{\partial z}, \quad (3)$$

ρ is the fluid density (with ρ_0 a reference value) and g is the acceleration due to gravity. This would also imply a corresponding lower limit on the internal deformation wavenumber,

$$k_d = f/(Nh), \quad (4)$$

of $k_d \geq 13 \text{ rad m}^{-1}$ for cases I and III and $k_d \geq 6.5 \text{ rad m}^{-1}$ for case II.

3b. Horizontal flow patterns

For each main experiment, the fluid in the tank was brought into solid-body rotation with the tank over a period of at least half a day prior to the start of the experiment, without any form of forcing. For the majority of experiments carried out, horizontal velocity fields were derived at 20 s intervals, beginning shortly after the initiation of convective forcing, and continued for as long as possible. In at least two cases, the flow continued to be monitored some time after the convective forcing was removed, thereby providing information on the decay of

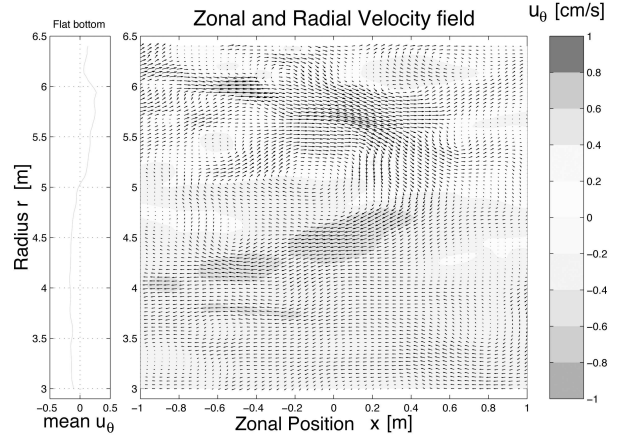

Figure 5: Horizontal flow field at mid-height in the Coriolis tank, rotating with a period of 40 s and with a flat bottom. Shaded contours are of azimuthal velocity in cm s^{-1} . The maximum vector length corresponds to a velocity of approximately 0.6 cm s^{-1} .

the turbulence field, due mainly to Ekman friction. The horizontal flow was typically measured at a level close to mid-depth (approximately 25 cm below the top surface in each case), although in at least two runs (with a flat bottom) a short sequence of measurements were made in which the horizontal flow field was sampled at a series of 5 different levels spanning the full depth of the tank.

i. Flat bottom flows The first case we consider is for a flat bottom, in which the fabric sheet was loosened sufficiently to lie at the bottom of the tank. In this case there is only a weak topographic gradient across the tank, due solely to the centrifugal distortion of the free upper surface. In practice at a rotation period $\tau_r = 40 \text{ s}$ this led to a mean slope in the top surface of around 0.65° and a corresponding value for β (cf Eq (1)) of $\sim 0.0036 \text{ m}^{-1} \text{ s}^{-1}$. Although this case corresponds most closely to an f -plane, therefore, there is a weak residual β -effect which should not be ignored. However, the effect is comparatively weak, and leads to characteristic length scales based on β (such as the ‘Rhines scale’

$$L_R = \pi (U_{\text{rms}}/\beta)^{1/2}, \quad (5)$$

where U_{rms} is a typical horizontal velocity scale based on the root mean square velocity fluctuations) which are comparable with the size of the tank. For Run I, for example, $L_R \simeq 2 \text{ m}$, indicating a ‘Rhines wavelength’ of around 4 m.

Fig. 5 shows a typical example of an equilibrated horizontal flow, taken from run I using the wide-angle camera. In this case, the flow is apparently dominated by a single, complex anticyclonic gyre, around 2m across

in radius though perhaps more extended in azimuth beyond the field of view. In addition, there is a general tendency for broadly retrograde drift in the azimuthal direction towards the outer radius and prograde drift in the inner part of the tank. This trend is clearly seen in the azimuthal mean azimuthal velocity profile in the left frame of Fig. 5. This overall pattern was seen to persist for long periods of the experiment, with the anticyclonic gyre remaining almost stationary, though evolving erratically in shape and intensity.

It was subsequently noted that the location of the inclined prograde jet on the inner flank of the gyre (at around $r = 4.5$ m and $x = 0$) coincided with some folds and irregularities in the fabric sheet which led to some residual topographic ridges 1-2 cm in height. It was possible, therefore, that some weak topographic effects were present to render the main flow pattern nearly stationary relative to the bottom of the tank. The weak differential azimuthal drift with radius is also in the same sense as might be expected from the residual effects of wind stress or drag, produced by differential motion between the moving surface of the tank and the stationary air in the laboratory, though it was difficult to estimate this effect theoretically. Nevertheless, the influence of these experimental imperfections needs to be borne in mind in interpreting these results.

ii. Sloping bottom flows In cases designated as having a sloping bottom, the fabric sheet was placed under tension between the tubular steel frame along the outer radius and a circular harness attached to the central post of the tank. This enabled a conically-sloping surface to be obtained, once the fluid in the tank had spun-up to solid-body rotation, with a slope angle of approximately 5° , decreasing the depth of the tank to around 25 cm at the inner radius of the annular channel (at $r = 2.5$ m). Several cases were run in this configuration, varying the buoyancy flux (by changing the density difference between the tank fluid and the spray) over around an order of magnitude. Good statistics, however, were only measured for a few cases owing to difficulties with flow visualisation and control of the spray forcing during the early phases of the experimental investigation.

For illustration, we present here results from a long duration experiment (case III, lasting some 6 hours) corresponding to a mean buoyancy flux of $4.5 \times 10^{-8} \text{ m}^2 \text{ s}^{-3}$ (i.e. comparable to the case I, discussed above), and with a rotation period of 40 s.

The appearance of the flow in this case is quite different to case I discussed above. Overall the flow is dominated by a mixture of small gyre-like eddies of typical diameter 0.5-1 m interspersed with meandering, azimuthally-oriented currents. The latter also appear clearly in the azimuthal mean azimuthal flow profile in the leftmost frame of Fig. 6, in which ‘jets’ of alternating sign are found with peak amplitudes of up to 0.5 cm

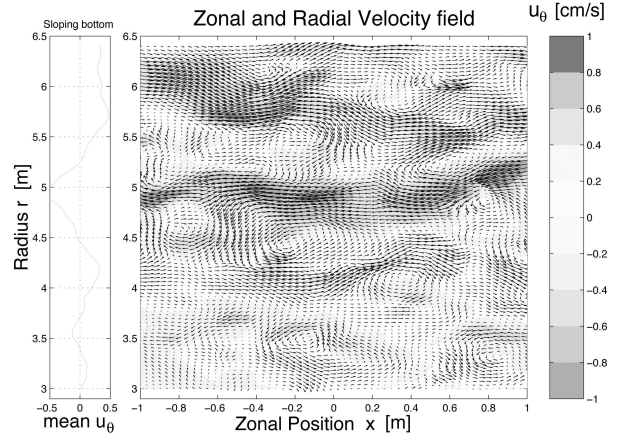

Figure 6: Horizontal flow field at mid-height in the Coriolis tank, rotating with a period of 40 s and with a sloping bottom. Shaded contours are of azimuthal velocity in cm s^{-1} . The maximum vector length corresponds to a velocity of approximately 0.6 cm s^{-1} .

s^{-1} . This banded organization of the zonal flow is also apparent in the shading of Fig. 6, in which clear stripes or bands oriented azimuthally are clearly seen. Flow near the outer boundary, however, is predominantly retrograde, much as for case I in Fig. 5.

Eddy gyres of either sign are apparent, though they typically are found at radii in which the vorticity of the azimuthal currents are of the same sign as the gyres. As discussed below, unlike in case I, these gyres continually evolve and, like other meanders in the azimuthal jets, translate azimuthally across the measurement domain, moving predominantly in the retrograde direction. Individual eddy gyres typically persisted for longer than the transit time across the field of view and formed reasonably coherent structures. They had a typical horizontal aspect ratio not far from unity, though their shape and orientation were found to evolve chaotically as they moved across the field of view.

iii. Time variations of jets As discussed above, the bottom slope was found to have a strong influence on the time evolution of the nonaxisymmetric eddies and gyres, with a tendency for stationary, non-propagating structures with a flat bottom and retrograde-propagating eddies with a sloping bottom. Such behaviour is suggestive of the eddies acting in a manner similar to Rossby waves, which propagate in a retrograde sense at a speed proportional to β . In the present case III, large-scale eddies with an azimuthal wavelength of around 1 m were seen to propagate azimuthally at a speed of around 2 mm s^{-1} across the domain at most radii.

During this time interval, however, the zonal flow pattern was also observed to evolve, although the ba-

sic qualitative character of the flows shown above were preserved.

In particular, cases with a sloping bottom were found to produce fields of relatively small vortices in association with an azimuthal mean flow with increasing amounts of structure and variability as the topographic β was increased. Such a trend is clearly shown in Fig. 7, which presents radius-time contour maps of azimuthal mean azimuthal velocity across the field of view of the narrow-angle camera. From these maps, it is clear that the flow breaks up into patterns of meandering zonal jets as β is increased. The position and amplitude of each jet is not constant, however, as apparent in Fig. 8, which shows a sequence from the strongest β case III over a longer time interval. But the flow evidently evolves erratically with time, with individual jets appearing to split and merge. The total number of jets, however, remains more or less the same throughout the period of observation, though it may be that some slow, systematic evolution is apparent. This might suggest that the jets are emerging during a long transient phase, even though the average kinetic energy of the flow reaches an equilibrium level within 1-2 hours of turning on the forcing. Such a possibility is discussed below in the context of other model studies.

3c. Vertical flow structure

Although the basic buoyancy-driven forcing of the flows was essentially baroclinic in character, various theoretical and modelling studies suggest (Salmon 1980) that the evolution of any upscale nonlinear energy cascade will lead to the excitation of large-scale flow components of an essentially barotropic character. Although time did not permit an extensive study of this aspect of the flow evolution, a few near-simultaneous measurements were made of the horizontal flow field at several levels in the vertical for one case with a flat bottom.

The flow was allowed to develop for several hours whilst buoyancy forcing was maintained at a constant value of around $F_0 \simeq 4 \times 10^{-8} \text{ m}^2 \text{ s}^{-3}$. Fig. 9 shows results from the near-simultaneous measurement of horizontal velocity at five vertical levels at a particular instant, spanning almost the full depth of the tank. Fig. 9(a) shows shaded contours of the vertically averaged flow, while (b) shows a map of the standard deviation of KE about that vertical mean. Thus, Fig. 9(a) may be regarded as representing the KE of the barotropic component of the flow, while Fig. 9(b) represents a measure of the baroclinic velocity field.

From these maps, it is clear that the vertically-averaged (barotropic) flow (i) contains much more kinetic energy than the standard deviation (baroclinic) components, by a factor of 10 in peak amplitude (note the difference in contour scale between Figs. 9(a) and (b)). In addition, (ii) the vertically-averaged flow appears to be dominated by relatively large-scale struc-

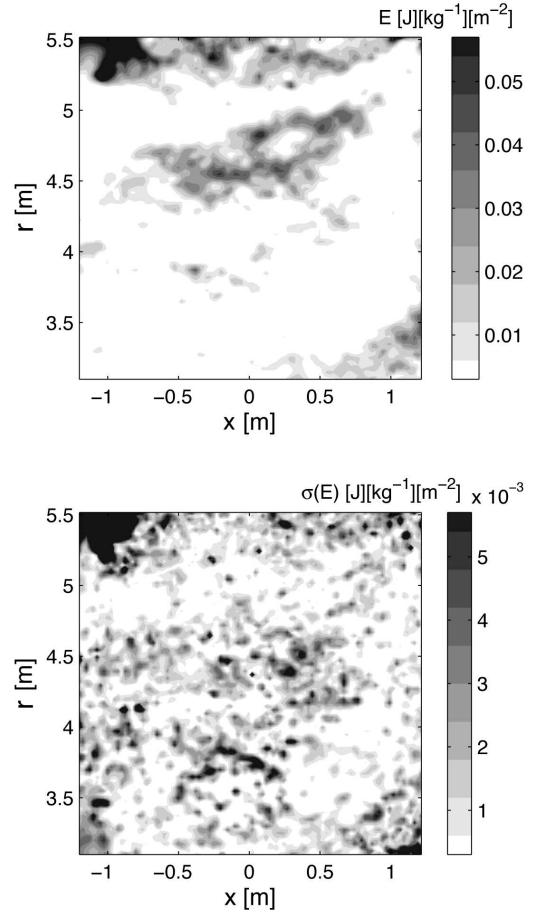

Figure 9: Instantaneous horizontal kinetic fields in the Coriolis tank, rotating with a period of 40 s and with a flat bottom. Shaded contours are of kinetic energy per unit mass (in units of $\text{J kg}^{-1} \text{m}^{-2}$) and show (a) the kinetic energy of the vertically-averaged flow and (b) the standard deviation of kinetic energy about the vertical mean.

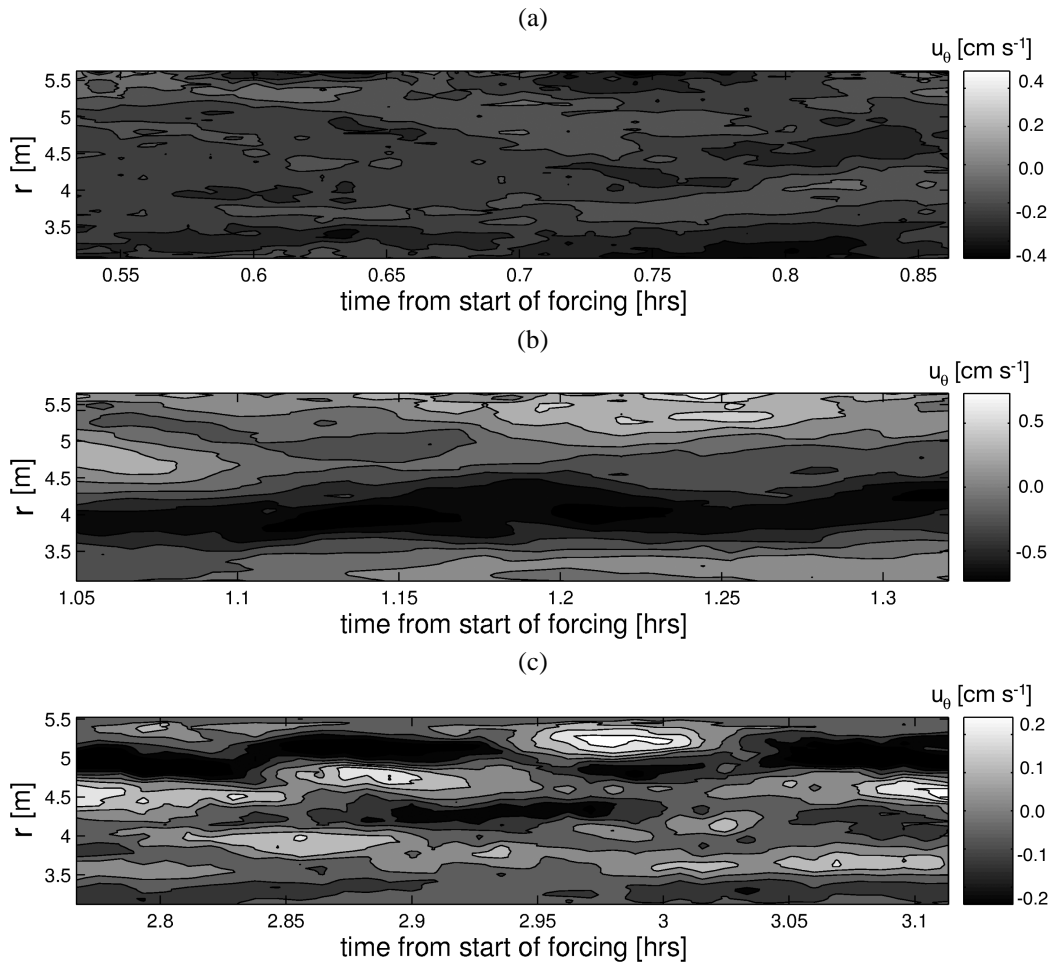

Figure 7: Azimuth-time contour plots of azimuthal mean azimuthal flow at mid-height in the Coriolis tank, for the three main cases discussed in the text: (a) case I (rotation period 40 s; flat bottom), (b) case II (rotation period 80 s, sloping bottom) and (c) case III (rotation period 40 s, sloping bottom). Shaded contours are of azimuthal velocity in cm s^{-1} .

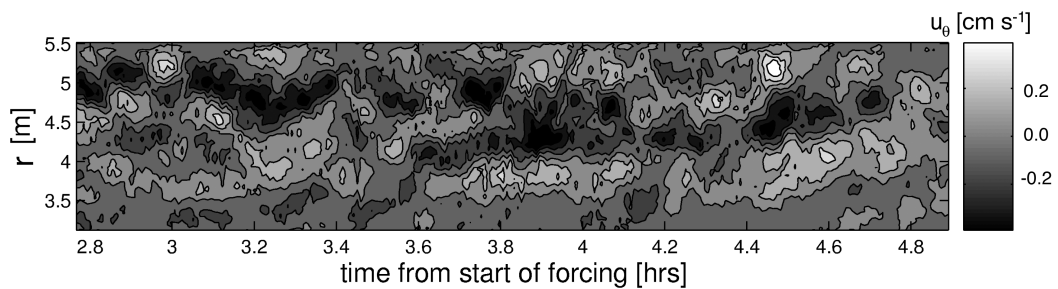

Figure 8: Azimuth-time contour plot of azimuthal mean azimuthal flow at mid-height in the Coriolis tank, for case III (rotation period 40 s, sloping bottom) over a period of approximately 2 hours. Shaded contours are of azimuthal velocity in cm s^{-1} .

tures, whilst the baroclinic standard deviation field is dominated by small-scale patches of KE, with a typical diameter of around 10-20 cm. Such a partitioning of scale and magnitude between the barotropic and baroclinic components of the flow is quite striking, and appears to demonstrate strongly the trends suggested from simple model studies in forming a strongly barotropic large-scale flow from a baroclinic (convective) energy input.

The typical scale of the baroclinic features presumably represents the horizontal size of individual convective plumes in the flow, with reference to Figs 3 and 4 above. It is of interest that this scale is comparable to the scale l_{rot} , defined by

$$l_{rot} \sim (3 - 5)(Ro^*)^{1/2}h, \quad (6)$$

and suggested by Fernando et al. (1991) and Marshall and Schott (1999) as a likely horizontal scale for rotationally-dominated convective plumes. Given the value of natural Rossby number $Ro^* \sim 3 \times 10^{-3}$ and $h \simeq 30\text{-}40$ cm, this would be expected to lead to $l_{rot} \sim 10\text{-}20$ cm, much as observed here in Fig. 9(b). Moreover, the observed velocity fluctuations in u_θ and w on the scale of the plumes is $O(1 \text{ cm s}^{-1})$, again consistent with the scalings suggested by Fernando et al. (1991) and Marshall and Schott (1999) of $|u, w| \sim \Omega l_{rot} \sim 1 - 2 \text{ cm s}^{-1}$.

4. Eddy-zonal flow interactions

In considering the origin of the large-scale barotropic flow discussed above, it was suggested that a form of up-scale nonlinear cascade of energy could be the mechanism responsible. In effect, this implies that the pattern of slowly-varying, barotropic zonal jets arise through direct interactions between non-axisymmetric eddies and the azimuthally-symmetric component of the flow. Such a possibility was effectively proposed for Jupiter's zonal jets by Ingersoll et al. (1981), who presented evidence from analyses of cloud-tracked winds derived from images from the Voyager 1 and 2 spacecraft. The evidence for this mechanism was later questioned by Sromovsky et al. (1982) because of possible biases caused by the non-uniform distribution of cloud tracers obtained by manual selection, though this result has subsequently been confirmed from Cassini data by Salyk et al. (2006). Read (1986) also raised additional doubts over the interpretation of this result, (a) because it was based on an assumption that barotropic motions dominated the flow in the Jovian troposphere, and (b) because the evidence was based on the correlation of the horizontal Reynolds stress component $\overline{u'v'}$ (where u is the zonal velocity component and v the northward velocity, and primes indicate departures from the zonal mean) with the lateral gradient of zonal flow $\partial\bar{u}/\partial y$, which provides a fundamentally non-local measure of zonal flow interaction.

Moreover, various other modelling studies appeared to suggest that large-scale non-zonal eddies might derive their energy from barotropic instability of the pattern of zonal jets, thereby linking this with the observed violations of the Rayleigh-Kuo stability criterion in the measured zonal jets around Jupiter's cloud tops.

4a. Reynolds stress accelerations

Similar issues must surely arise in the present experiments, though in this case we have already established that the large-scale flow (including, presumably, the main eddies resolvable in our measurements) is predominantly barotropic. Given detailed, accurate and representative measurements of horizontal velocity fields, well-sampled in time and covering a sufficient area of the flow to obtain meaningful statistics, it is feasible directly to derive not only the pattern of horizontal Reynolds stress at each timestep for which velocities are measured, but also the divergence of this Reynolds stress and hence the implied eddy-induced acceleration of the azimuthal mean zonal flow. In cylindrical geometry (e.g. see Pfeffer et al. (1974), Read (1985)), the full azimuthally-averaged zonal momentum equation reduces to

$$\begin{aligned} \frac{\partial\bar{u}}{\partial t} &= (2\Omega + \bar{u}/r)\bar{v} - \bar{v}\partial\bar{u}/\partial r & (7) \\ [1] & \quad [2] \quad [3] \\ & - \bar{w}\partial\bar{u}/\partial z - \frac{1}{r}\partial/\partial r(r\overline{u'v'}) + \\ & \quad [4] \quad [5] \\ & \frac{\partial}{\partial z}(\overline{w'u'}) + \overline{F^{(x)}} \\ & \quad [6] \quad [7] \end{aligned}$$

(cf Andrews et al. (1987); Eq (3.3.3)) where u , v and w are now respectively the azimuthal, radial and vertical velocity components. $F^{(x)}$ represents residual forces e.g. due to molecular viscosity and/or wind stresses. Term [2] represents the combined Coriolis and centrifugal acceleration due to zonal mean meridional flow, while [3] and [4] represent advection of zonal momentum by \bar{v} . Terms [5] and [6] represent accelerations due to the divergence of the Reynolds stresses. If the present experiment develops zonal jets via the same barotropic nonlinear zonation mechanism as is believed to be responsible for the development of zonal jets in the numerical simulation studies discussed above, the zonal acceleration [1] should be dominated by the effects of term [5] representing the divergence of the *horizontal* Reynolds stress. Moreover, this balance should be realized independently of height z . Thus, if the zonal flow is indeed a direct result of barotropic eddy-zonal flow interactions, it should be possible to compare independent measurements of both the horizontal Reynolds stress divergence and actual changes in the azimuthal mean flow at any height in the flow.

In Fig. 10 the results of such a comparison are shown,

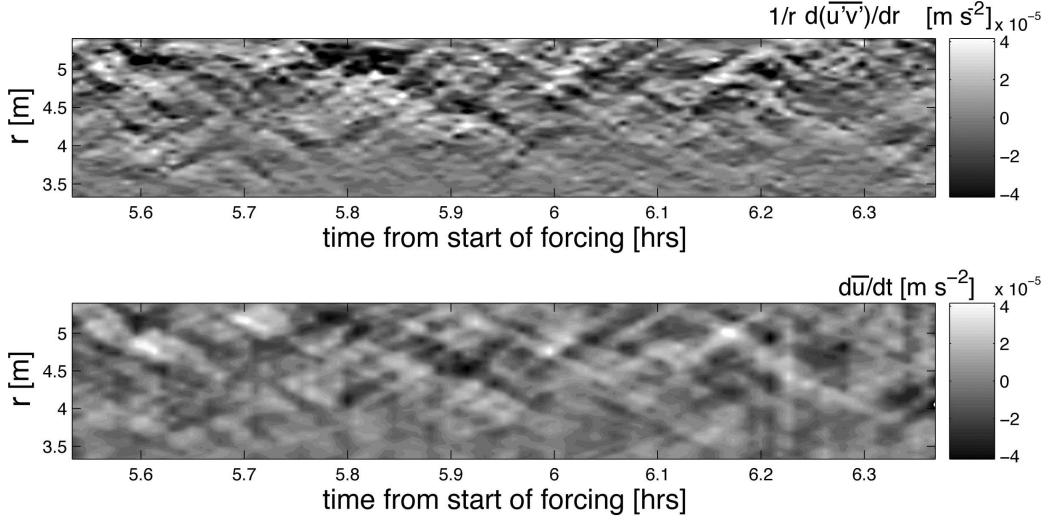

Figure 10: Measurements of the divergence of the horizontal Reynolds stress (a) in an equilibrated convectively-driven flow with a sloping bottom (case III), compared with (b) the measured acceleration $\partial\bar{u}/\partial t$ of the mean azimuthal flow, as determined by finite time-differencing. Measurements cover a period of approximately 1 hour, sampled twice per rotation period.

for the case III with the most highly developed pattern of zonal jets featured above. In Fig. 10(a) shaded contours of the instantaneous divergence of the measured Reynolds stress are shown, sampled twice per rotation period for a total interval of around 1 hour. By this time the forcing had been applied continuously for several hours and the flow seemed to have reached a reasonably equilibrated level of kinetic energy. In Fig. 10(b), measurements are shown of the acceleration of the azimuthal mean zonal flow $\partial\bar{u}/\partial t$, obtained by differencing the profile of azimuthal mean flow in successive timesteps using centred differences. Both fields appear to be quite noisy, with many patches of both positive and negative accelerations apparent in each field, apparently fluctuating back and forth and mostly concentrated in the outer half of the annular channel. Even so, there are some similarities apparent in the spatial variations of both fields, suggesting that they could be correlated.

Fig. 11 shows the result of forming the correlation coefficient $\mathcal{C}(r, \tau)$, computed as a function of radius and averaged over all timesteps in the narrow angle dataset for case III, between the two quantities plotted in Fig. 10. The definition of \mathcal{C} is given by Eq (8) below

$$\mathcal{C}(r, \tau) = \frac{\langle \bar{u}_t(r, t + \tau) \cdot (div.\bar{u}'v'(r, t)) \rangle}{[\langle (\bar{u}_t(r, t))^2 \rangle \langle (div.\bar{u}'v'(r, t))^2 \rangle]^{1/2}}, \quad (8)$$

(where angle brackets denote the time average, the subscript t denotes time derivative and $div.\bar{u}'v' = 1/r\partial/\partial r(r\bar{u}'v')$) and allows for the possibility of a time lag in the response between the Reynolds stress divergence and the azimuthal mean zonal flow itself. The results show a clearly peaked response in correlation

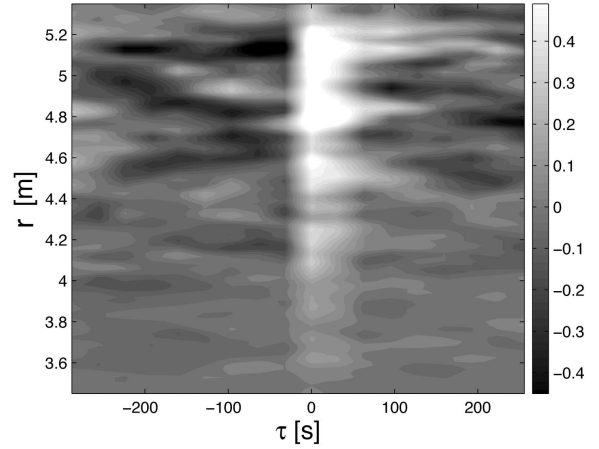

Figure 11: Shaded contour map of the correlation coefficient between the horizontal Reynolds stress divergence and the zonal flow acceleration in an equilibrated convectively-driven flow with a sloping bottom (case III). Covariance is plotted as a function of radius and time lag between the measurement of Reynolds stress and acceleration. Measurements are averaged over a period of approximately 1 hour, sampled twice per rotation period.

close to lag zero ($\tau = 0$) and of magnitude up to 0.5, though with a tendency for the acceleration to respond slightly after the measured Reynolds stress event. There is a clear cut-off on the negative lag (time lead) side of the origin at all radii, with a more gradual decay in correlation with time lag in the positive lag direction. This is a clear signature that the horizontal Reynolds stress is strongly correlated with the measured zonal flow acceleration, and is entirely consistent with the hypothesis that horizontal Reynolds stress plays a major role in controlling and influencing subsequent changes in the behaviour of the pattern of azimuthal mean flow. However, it is somewhat surprising that the zonal acceleration takes place following a short time delay. The explanation for this is not clear in the present work, though may indicate a finite time interval needed for disturbances detected at the mid-plane to propagate their influence throughout the water column.

The magnitude of the implied conversion of kinetic energy from eddies into the zonal flow, corresponding to $-\bar{u}/r\partial(\overline{ru'v'})/\partial r$ integrated over the domain, is around $3.0 \times 10^{-8} \text{ W kg}^{-1}$, which may be compared with the computed value for the rate of change of zonal kinetic energy $\partial(u^2/2)/\partial t$ of $3.2 \times 10^{-8} \text{ W kg}^{-1}$ for case III. Thus, the Reynolds stresses can account for more than 90% of the energy fluctuations in the zonal flow for this case. The missing remainder may represent the effects of measurement errors, but could also reflect other sources of zonal acceleration e.g. due to vertical Reynolds stresses associated with baroclinic (convective) exchanges on small scales, and also the direct effects of wind stresses. The latter are almost certainly dominant for case I, for which Reynolds stresses are too weak to account for observed accelerations.

5. Kinetic energy spectra and energy transfers

Numerical studies of small-scale forced, two-dimensional turbulent flows on the sphere or β -plane which develop systems of parallel zonal jet streams are often found to develop strongly anisotropic kinetic energy spectra with various characteristic properties. Given the importance of inertial up-scale energy cascades in such flows, the form of the energy spectra may be diagnostic of various important aspects of the turbulent dynamics shaping the equilibrated flow. In particular, the logarithmic slope of the energy spectrum may indicate the nature of energy transfers between scales in different directions. But for equilibrated spectra with a constant energy injection rate ϵ (in units of $\text{m}^2 \text{ s}^{-3}$), introduced at small scales, the upscale energy-cascading kinetic energy spectrum is expected to tend to the quasi-universal ‘Kolmogorov 5/3 law’ (Kolmogorov 1941),

$$E_R(k) = C_K \epsilon^{2/3} k^{-5/3} \quad (9)$$

(later generalized by Kraichnan (1967) and Batchelor (1969) to two-dimensional turbulence, and hereafter referred to as ‘KBK’), where C_K is a universal dimensionless constant $\simeq 4 - 6$ and k is the total (isotropic) wavenumber (in m^{-1}). In the direction perpendicular to the zonal flow (i.e. increasing latitude on a spherical planet, or cylindrical radius as here), however, various studies have suggested that the spectrum may equilibrate towards a different, and significantly steeper, form

$$E_Z(k) = C_Z \beta^2 k^{-5}, \quad (10)$$

(where C_Z is another universal dimensionless constant $\simeq 0.3 - 0.5$) provided certain conditions are fulfilled (see Galperin et al. (2006) for further discussion). Such conditions mainly relate to the respective sizes of the scales of energy injection (which need to be small enough) and those scales affected by large-scale energy removal (i.e. at wavenumbers less than the so-called ‘frictional wavenumber’ k_{fr} ; see Galperin et al. (2006) and references therein).

5a. Spectral slopes and anisotropies

In the present series of experiments, the previous sections have indicated that the convectively driven turbulent flows result in the formation of jet-like, zonally-elongated structures which appear to be the result of up-scale nonlinear interactions, including strong and coherent interactions with the azimuthally-symmetric component of the zonal flow. It is of interest, therefore, to examine whether the kinetic energy spectra reveal any similarities with those obtained in idealized numerical model studies.

Fig. 12 shows kinetic energy spectra for each of the three main cases discussed above, illustrating the influence of increasing β on the equilibrated energy spectra. In the flat bottom experiment (Fig. 12(a)), the total and non-zonal spectra appear to follow closely a $-5/3$ slope over the full range of wavenumbers from around $5-50 \text{ rad m}^{-1}$, beyond which the spectrum steepens for $k > 50$. The zonal spectrum in fact follows a slope close to $-8/3$, broadly consistent with an isotropic energy spectrum, with no evidence of any steepening at the lowest wavenumbers accessible in these measurements. The amplitude of the total energy spectrum is approximately 40% below the expected KBK spectrum for $C_K = 5$ using the value of ϵ estimated from $\epsilon \simeq E_k/\tau_E$, though the reason for this is not clear.

Fig. 12(b) shows the intermediate β case with the full sloping bottom but half the rotation rate Ω . In this case the non-zonal and total energy spectra have a somewhat steeper slope than $-5/3$ over the range $5 \leq k \leq 50 \text{ rad m}^{-1}$, though with an amplitude approaching that of the expected KBK spectrum around $k \leq 10 \text{ rad m}^{-1}$.

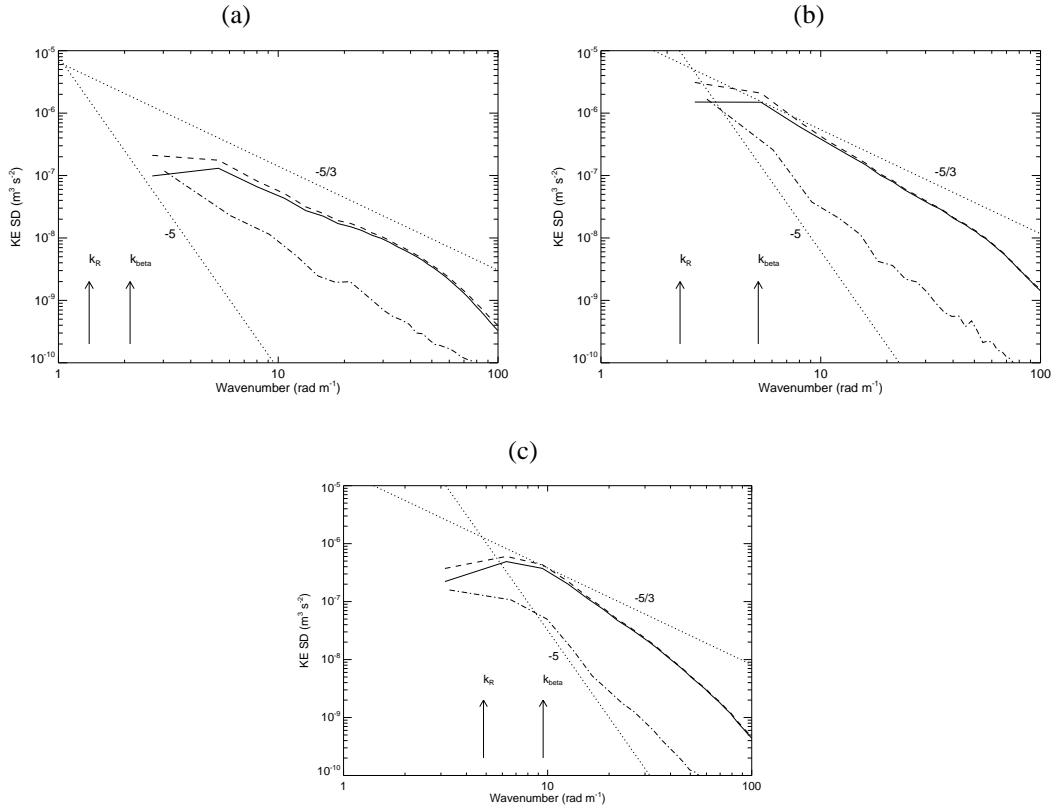

Figure 12: Kinetic energy spectra for the three main cases (a) I, (b) II and (c) III. Graphs show the non-zonal isotropic kinetic energy (solid lines), total kinetic energy (dashed lines) and the kinetic energy of the azimuthal mean flow (dashed-dotted lines), all in units of energy per unit mass per unit wavenumber as a function of wavenumber (rad m^{-1}). Dotted straight line segments indicate the spectral slopes of $-5/3$ and -5 . The lines labelled -5 indicate segments of spectra given by Eq (10) and those labelled $-5/3$ by Eq (9) with $C_K = 5$ in both slope *and magnitude*. Data were obtained by CIV analyses of images from the narrow angle camera.

In contrast to case I, however, the zonal spectrum exhibits a $-8/3$ slope only for $k > 9 \text{ rad m}^{-1}$, becoming significantly steeper for lower values of k . This indicates that the kinetic energy distribution is starting to become somewhat anisotropic at low wavenumbers, at least qualitatively consistently with numerical studies on the β -plane. It is of interest to note that the steepening of the zonal spectrum occurs around a wavenumber comparable to or somewhat greater than k_β ($\sim 5.5 \text{ rad m}^{-1}$ for this flow). At the lowest wavenumbers, the non-zonal spectrum clearly flattens for $k \leq 5 \text{ rad m}^{-1}$. Spectra obtained from wide-angle images (not shown) indicate a flattening of the non-zonal spectrum around $k \sim 3 \text{ rad m}^{-1}$, indicating a value for k_{fr} of around 3 rad m^{-1} , which is comparable to the radial wavenumber of the zonal jets.

The strongest β case in Fig. 12(c) shows some even clearer signs of anisotropic structure, though evidence for the classical KBK $-5/3$ slope is not very clear. However, the total and non-zonal spectra become tangent to the KBK form around $k = 10 \text{ rad m}^{-1}$, and in corresponding spectra obtained using the wide-angle camera (not shown) there is clearer evidence for a segment of the spectrum with a slope of $-5/3$ for $\sim 6 \leq k \leq 12 \text{ rad m}^{-1}$. The non-zonal and total energy spectra appear to rise to a peak at around $k = 6 \text{ rad m}^{-1}$, flattening or even decreasing as k decreases below $\sim 6 \text{ rad m}^{-1}$, again suggesting a value for k_{fr} of around 6 rad m^{-1} which, as in case II, corresponds closely to the radial wavenumber of the zonal jets. At smaller scales ($k > 50 \text{ rad m}^{-1}$) the spectrum steepens, perhaps approaching the -3 slope characteristic of an enstrophy-cascading range in 2D turbulence (sometimes known as ‘Kraichnan’s -3 Law’; Kraichnan (1967)). At these scales, however, corresponding to a horizontal wavelength of $< 10 \text{ cm}$, the flow is almost certainly dominated by three-dimensional baroclinic effects, and perhaps even viscous effects at the smallest scales. The azimuthal mean spectrum is significantly steeper than $-8/3$ for $6 < k < 15 \text{ rad m}^{-1}$, indicating fairly strongly anisotropic structure biased towards accumulation of energy in zonal modes at low wavenumber. We plot in Fig. 12(c) a straight line segment with the slope -5 and magnitude consistent with Eq (10) for comparison with the measured zonal spectrum. In this case both the slope and the magnitude of the zonal spectrum are actually comparable with the theoretical spectrum suggested e.g. from the model studies of Huang et al. (2001) and Sukoriansky et al. (2002). Such a trend is somewhat evident for case II, though not at all for case I.

The role of wind stress in adding a directly driven component of the zonal flow in each case here may partly underly why the effects of anisotropic inertial energy cascades are difficult to identify in those cases where β -effects are relatively weak. It was mentioned above that wind stresses may be partly responsible

for the presence of predominantly retrograde azimuthal flow near the outer boundary of the experiment. It is only in the case with the strongest β -effect that a possible influence of the anisotropic energy cascade becomes apparent in the zonal energy spectrum, even though some weak indication of zonation in the azimuthal flow is apparent in the intermediate β case II.

5b. Spectral transfer rates

The evolution of the anisotropic spectra discussed above is determined by the nature of the nonlinear interactions between various wavenumber components in the flow. Thus far we have concentrated on examining some of these interactions in the physical domain, by examining directly the energetic exchanges between the azimuthal mean (zonally-symmetric) flow and the non-axisymmetric eddies. However, most theoretical treatments of energy cascades consider exchanges within the spectral domain, by examining the transfer of energy from one region of the spectrum to another in wavenumber space. Anisotropy is then revealed in the channelling of energy in particular directions in wavenumber space.

Chekhlov et al. (1996), for example, computed a two-dimensional enstrophy transfer function in Fourier (wavenumber) space from a sequence of direct numerical simulations of β -plane turbulence. Starting with the enstrophy evolution equation,

$$\left[\frac{\partial}{\partial t} + 2\nu k^2 \right] \Xi(\mathbf{k}, t) = \mathcal{T}_\Xi(\mathbf{k}, t), \quad (11)$$

where $\Xi(\mathbf{k}, t)$ is the vorticity correlation function, ν is the kinematic viscosity of the fluid, \mathbf{k} is the horizontal wave vector and k its magnitude. The spectral enstrophy transfer, $\mathcal{T}_\Xi(\mathbf{k}, t)$, is then given by

$$\mathcal{T}_\Xi(\mathbf{k}, t) = 2\pi k \mathcal{R} \left[\int_{\mathbf{p}+\mathbf{q}=\mathbf{k}} \frac{d\mathbf{p}d\mathbf{q}}{4\pi^2} \times \frac{\mathbf{p} \times \mathbf{q}}{|\mathbf{p}|^2} \langle \zeta(\mathbf{p}, t) \zeta(\mathbf{q}, t) \zeta(-\mathbf{k}, t) \rangle \right] \quad (12)$$

where $\zeta(\mathbf{k}, t)$ is the relative vorticity as a function of wavenumber \mathbf{k} at time t , \mathbf{p} and \mathbf{q} are wave-vector variables of integration, \mathcal{R} denotes the real part and angle brackets denote the ensemble average. To compute a spectral energy transfer map in \mathbf{k} -space, a cut-off wavenumber k_c was introduced such that the energy injection into mode \mathbf{k} is taken into account only via triads involving other modes with $|\mathbf{k}| > k_c$. The \mathbf{k} -dependent net time-averaged enstrophy transfer into mode \mathbf{k} , $\mathcal{T}_\Xi(\mathbf{k}|k_c)$, was then computed for each mode \mathbf{k} such that $|\mathbf{k}| < k_c$ (the so-called ‘explicit’ modes), by integrating Eq (12) over all other modes with wave-vectors \mathbf{p} and \mathbf{q} for which $|\mathbf{p}|$ and $|\mathbf{q}| > k_c$ (the ‘implicit’ modes), replacing the ensemble average with the time-mean spectral covariance. The corresponding

time-averaged energy transfer function $\mathcal{T}_E(\mathbf{k}|k_c)$ can then be computed from

$$\mathcal{T}_E(\mathbf{k}|k_c) = \frac{\mathcal{T}_\Xi(\mathbf{k}|k_c)}{|\mathbf{k}|^2}. \quad (13)$$

Chekhlov et al. (1996) and Galperin et al. (2006) computed the integral in Eq (12) for their DNS3 run, and this clearly showed a strong tendency for energy to accumulate into particular wavenumbers along the k_y axis, consistent with the formation of strong zonal jets on a scale $< k_c$.

In the present experiments, we have computed the same spectral energy transfer function in two dimensions, using the measured vorticity fields at mid-depth discussed above. Fig. 13 shows two examples of such functions, computed from sequences of vorticity fields derived from images from the narrow angle camera. Fig. 13(a) shows the resulting kinetic energy transfer function for the flat bottom (Case I), which indicates a general trend for upscale energy transfer towards the low wavenumber region around $|\mathbf{k}| = 5-10 \text{ rad m}^{-1}$. There is also apparently a weak tendency for the accumulation of kinetic energy into two peaks at \mathbf{k} around $(\mp 3, \pm 3) \text{ rad m}^{-1}$. This is consistent with the form of the velocity fields within this field of view shown above, with persistent diagonal flows across the domain in association with a near-stationary domain-filling eddy with a diameter $\geq 2 \text{ m}$.

For the sloping boundary, on the other hand, a clearer pattern is found to emerge. Fig. 13(b) indicates a clear tendency for kinetic energy to accumulate from $|\mathbf{k}| > k_c$ into a roughly circular ring in wavenumber space with a radius of around $8-10 \text{ rad m}^{-1}$, but with clear maxima close to the k_y axis at $k_y = \pm 8 \text{ rad m}^{-1}$. The maxima are roughly twice the strength of the isotropic ring in $\mathcal{T}_E(\mathbf{k}|k_c)$, indicating a modest accumulation rate of kinetic energy into zonally elongated structures with a wavelength of a little less than 1 m . Such a wavelength is roughly consistent with the development of the zonal jets described above, though indicates a much weaker tendency for strong jet formation than in the much clearer example presented in the numerical model simulations of Chekhlov et al. (1996) and Galperin et al. (2006).

6. Potential vorticity dynamics

Potential vorticity almost certainly plays at least as important a role in the dynamics of the observed jets and vortices in the experiment as their energetics. In particular, the formal stability of the observed flows is generally expressed using criteria formulated in terms of potential vorticity and its gradient. In this section, therefore, we compute diagnostics relating to a potential vorticity q based on a barotropic (shallow water) formula-

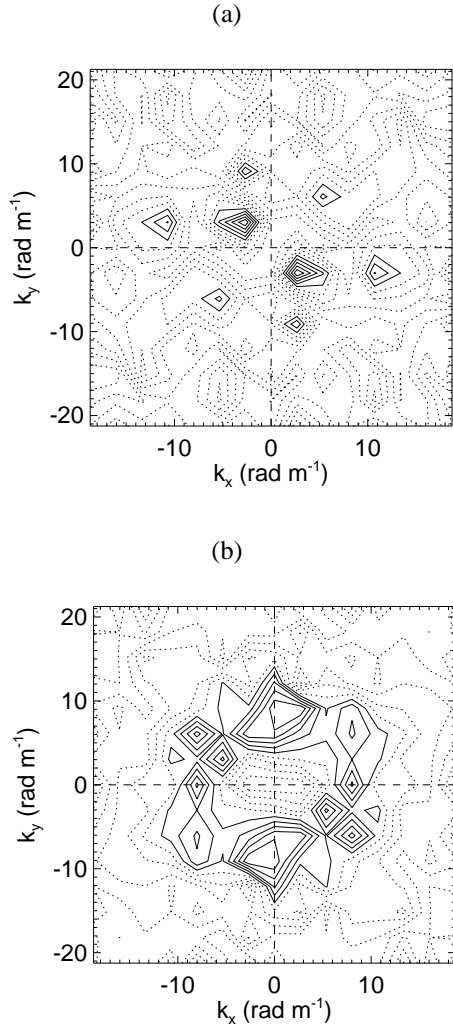

Figure 13: Normalized spectral energy transfer functions for (a) Case I (flat bottom) and (b) Case III (sloping bottom, full β). Functions were computed from sequences of vorticity fields obtained from narrow angle camera images, and integrated over triangles in wavenumber for $k_c \simeq 20 \text{ rad m}^{-1}$, averaging in time over approximately 40-50 rotation periods. The field of $\mathcal{T}_E(\mathbf{k}|k_c)$ is normalized in each case by the maximum value in the field. Contours are shown with interval 0.1 and contours below 0.5 are dashed.

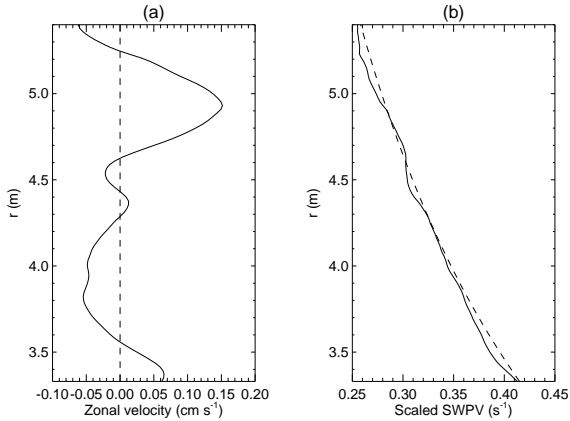

Figure 14: (a) Radial profile of the azimuthal and time mean azimuthal velocity, and (b) the corresponding profile of (shallow water) potential vorticity (see text), averaged over a period of approximately 1 hour from velocity fields acquired from the narrow angle camera.

tion

$$q = \frac{2\Omega + \zeta}{h(r)}, \quad (14)$$

where ζ is the relative vorticity measured at mid-depth. This can be determined relatively easily using the vorticity fields measured via CIV and knowledge of the variation of the depth of the tank due to the sloping lower and upper boundaries.

6a. Rayleigh-Kuo stability

Fig. 14 shows radial profiles of the time and azimuthal mean azimuthal velocity and corresponding potential vorticity, averaged over approximately one hour of the late phase of the experiment. From these profiles it is clear that there are some zonal jet-like structures which survive the time-averaging, but the potential vorticity profile associated with this profile of \bar{u} is evidently monotonic in radius. Such a result would suggest that the spatio-temporal mean azimuthal flow is consistent with a state of neutral stability with respect to the Rayleigh-Kuo criterion for barotropic stability.

On shorter timescales, however, the stability status of the azimuthal flow profile is less clear. Figs 15 and 16 show the equivalent profiles of $\bar{u}(r)$ and $\bar{q}(r)$ for an example of an instantaneous flow (Fig. 15) and a shorter term time average (this time over just 300 s; Fig. 16). In the first case, the instantaneous profile of \bar{u} shows a stronger and more complex array of zonal jets in association with a q profile which is clearly non-monotonic. Indeed $\partial q / \partial r$ clearly changes sign in Fig. 15(b) several times, indicating positive violations of the Rayleigh-Kuo stability criterion consistent with active barotropic instability. Sharp positive gradients in \bar{q} occur in association with prograde peaks in \bar{u} , while weak or reversed

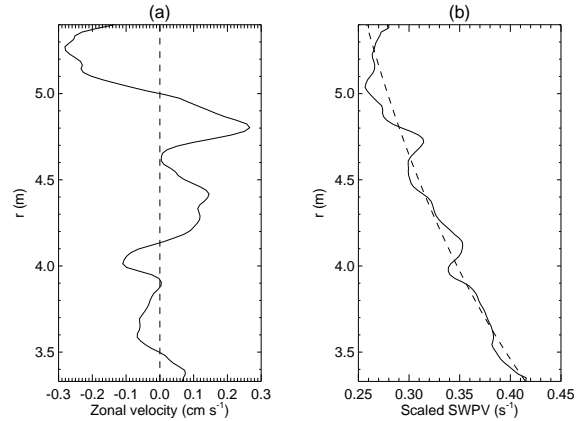

Figure 15: Radial profiles of the azimuthal mean azimuthal velocity (a) and the corresponding profile of (shallow water) potential vorticity (b) (see text) for a typical instantaneous flow from Case III in the rotating tank with sloping bottom. Velocity fields were acquired from the narrow angle camera.

gradients in \bar{q} are found associated with retrograde azimuthal jets. This is much as found in idealised models of active Rossby wave critical layers (e.g. see Haynes (1989)). Similar traits are also found in the PV structure of Jupiter's atmosphere (Read et al. 2006) in association with the cloud-level zonal jets.

If the profiles are averaged over an intermediate time scale, however, the violations of the Rayleigh-Kuo stability criterion are less marked but still evident, with clear indications of a PV 'staircase' with radius. Fig. 16(a) and (b) shows profiles averaged over an interval of just 300 s around the time of the instantaneous flow in Fig. 15(a) and (b). This would seem to indicate a tendency for persistent barotropic instability on timescales of a few hundred seconds, beyond which the instability is able to eliminate the regions of reversed $\partial \bar{q} / \partial r$ in the PV 'hyperstaircase' found on short timescales. Such a process would constitute a form of 'barotropic adjustment', in which the time-averaged flow on long timescales approaches a state of near-neutral stability with regard to PV gradients. The mechanism for this is almost certainly a manifestation of a form of Rossby wave breaking, in which PV gradients become temporarily reversed as waves reach a large enough amplitude to overturn.

7. Discussion

Our objectives in carrying out this experiment were to seek to create conditions in the laboratory which could capture, at least qualitatively, some aspects of the dynamical regime which might characterize the banded circulation observed in the gas giant planets, and per-

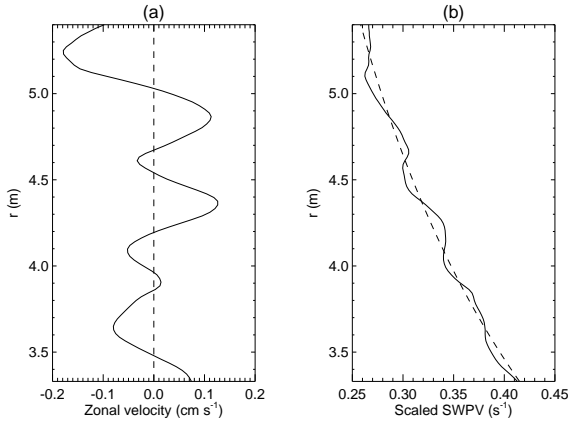

Figure 16: Radial profiles of the azimuthal and time mean azimuthal velocity (a) and the corresponding profile of (shallow water) potential vorticity (b) (see text) for a flow averaged over a period of 300 s around the time of the snapshot in Fig. 15 above. Velocity fields were acquired from the narrow angle camera.

haps the recently discovered zonally-banded currents in the Earth’s oceans. Such a goal turns out to be far from trivial, since (as we discuss below) the relevant regime is difficult to achieve on a laboratory scale because of various conflicting scaling requirements. The present experiments were made possible as a result of an all-too-brief opportunity (for 6 weeks in 2002) to carry out a collaborative investigation with the team at the Coriolis facility in Grenoble, which provided the best available resources to access the conditions necessary for nonlinear zonation. However, the difficulties of such an experiment should not be underestimated, and our experimental programme in the end was able to sample adequately only a few points in the parameter space of the system. Nevertheless, from the results obtained we were able to obtain clear evidence of the processes anticipated, in association with a form of small-scale convective forcing which is as close as possible to a ‘natural’ means of flow excitation as could be envisioned within a terrestrial laboratory. An analysis of the properties of these flows obtained in the laboratory, therefore, ought thereby to provide important insights into the dynamical mechanisms at work within such a regime, and to allow us to put several previously proposed mechanisms for zonal jet formation and maintenance to some severe experimental tests.

7a. Zonostrophic regime

Galperin and co-workers (Sukoriansky et al. 2002; Galperin et al. 2006) have attempted to define such a regime, dominated by the nonlinear generation of zonal jets (termed the ‘zonostrophic’ regime), based on extensive studies using idealized barotropic numerical model

simulations, as one in which

- (a) the flow is forced on relatively small scales (compared with those of the physical domain),
- (b) an inertial range exists over a large enough range of scales such that the β -effect can exert sufficient influence on the flow to allow anisotropic interactions to develop fully,
- (c) large-scale ‘friction’ (i.e. removal of energy at large-scales) is sufficiently small to permit (b) yet enough to prevent the accumulation of energy in the largest (domain-filling) modes of the system.

The existence of such a ‘universal’ regime has been disputed e.g. by Danilov and Gurarie (2002), though subsequently Galperin et al. (2006) and Sukoriansky et al. (2007) have claimed that the cases considered by Danilov and Gurarie (2002) did not lie in the appropriate region of parameter space. Galperin et al. (2006) proposed a series of chain inequalities as a means of formulating a set of criteria for identifying the range of parameters over which such a regime might occur. In the present context, these can be expressed in the form

$$k_{\xi} \geq 2k_{\beta} \geq 8k_{\text{fr}} \geq \frac{30\pi}{L}, \quad (15)$$

where k_{ξ} is a wavenumber (in units of rad m^{-1}) characteristic of the scales of energy input/forcing, k_{β} is defined as

$$k_{\beta} = \left(\frac{\beta^3}{\epsilon} \right)^{1/5} \quad (16)$$

(where ϵ is the rate of input of kinetic energy into the upscale cascade by the forcing, in units of $\text{m}^2 \text{s}^{-3}$) and represents the scale at which the Rossby wave period is comparable with the eddy overturning timescale, k_{fr} is the ‘frictional’ wavenumber determined by the balance between upscale energy transfer and energy removal at large scales, and L represents the physical horizontal scale of the domain (in the present case the radius of the apparatus $L = 6.5 \text{ m}$). Given sufficient time to evolve, flows which satisfy Eq (15) are expected to develop self-similar energy spectra which adopt the ‘universal’ forms given in Eqs (9) (over most angles ϕ) and (10) (close to $\phi = \pm\pi/2$) over discernible regions of their spectra. Under such circumstances, the zonal component of the energy spectrum (given by Eq (10)) can be integrated over wavenumber and shown (e.g. Galperin et al. (2001), Galperin et al. (2006)) to lead to $k_{\text{fr}} \simeq k_R$ to within a factor $\text{O}(1)$, where

$$k_R = (\beta/U_{\text{rms}})^{1/2} = \frac{\pi}{L_R} \quad (17)$$

is the Rhines wavenumber (cf Eq (5)). Thus, in this regime k_R and k_{fr} are more or less interchangeable as estimates of the meridional scale favoured by the flow

for the emergence of banded zonal jets. Most recently, Sukoriansky et al. (2007) have further elucidated this relationship between k_{fr} and k_R , noting that forced-dissipative flows for which $k_\beta \geq 2k_R$ will exhibit most of the salient properties of the zonostrophic regime, whilst those for which $k_\beta \leq 1.5k_R$ will lie in the so-called frictionally-dominated regime and will not exhibit significant zonostrophic inertial ranges.

Table 2 presents estimates of the main parameters invoked in Eq (15), derived from the experimental parameters noted in Table 1 above and the apparatus dimensions. k_ξ is estimated as $2\pi/l_{rot}$, where l_{rot} is computed using Eq (6) above, and k_β is obtained from Eq (16). Note that the estimates of ϵ used here were obtained as $\epsilon \simeq U_{rms}^2/(2\tau_E)$, where τ_E is the Ekman spin-down timescale ($= h/\sqrt{\nu\Omega}$); see Table 1. This typically results in a value for ϵ around 3-15% of the input buoyancy flux F_B , which is not unreasonable since it is likely that only a small fraction of the energy input associated with F_B will actually be utilised in the nonlinear inverse energy cascade (cf the estimates used by Galperin et al. (2006) for the oceans and gas giant planets). k_{fr} represents the dominant wavenumber at which large-scale friction exerts a strong influence on the energy spectrum, and is estimated from the low wavenumber peak or break in the total or zonal wavenumber spectrum for each case.

From these estimates, it is apparent that, although each experiment satisfies the first inequality in Eq (15), Cases I and II do not rigorously satisfy either of the remaining two criteria for the zonostrophic regime. Case III, however, with the strongest β -effect, comes the closest to fulfilling all of the criteria, with $k_\beta \simeq 2k_R$. For case II, our estimates of k_β and k_R are probably too close together to allow much of an inertial range to develop between them, placing it on the margins of the zonostrophic and frictionally-dominated regimes. As discussed further by Galperin et al. (2006), this section of the spectrum is critical for the emergence of the fully-formed k^{-5} spectrum in the zonal flow, and the separation of k_β and k_{fr} or k_R is much greater for the outer gas giant planets than could be obtained in our experiments here. This may well help to account for why our banded zonal jets are much less dominant in the laboratory than are typical in the atmospheres of Jupiter and Saturn. Even so, the flows obtained in Case III do show a number of features suggestive of the zonostrophic regime, indicating that we were able to enter at least the margins of this class of dynamical behaviour. Galperin et al. (2006) note that the oceans also do not quite satisfy the criteria on k_β/k_{fr} set out in Eq (15), though fulfill them somewhat more clearly than in our experiment III.

Also included in Table 2 are estimates of wavenumber scales based on both the internal and external deformation radii. k_d is defined in Eq (4), though only a

lower limit can be estimated because N is poorly defined. The external deformation scale is estimated from $k_{dext} \sim f/\sqrt{gh}$, though this wavenumber turns out to be much less than the smallest wavenumber that can be accommodated in the annular domain. These estimates suggest that the external deformation radius does not play a role in the dynamics of this experiment, but internal baroclinic disturbances could be of significance. However, there is no evidence of scales of motion which manifest themselves as different from those represented by k_β , k_R or k_ξ .

7b. Scales and spectral transfers

Insofar as our Experiment III does lie parametrically in the zonostrophic regime, therefore, the diagnostics computed above help to reveal the dynamical mechanisms at work in sustaining a zonally-banded circulation. We have shown that, provided β is strong enough, a flow excited by stirring at small scales will evolve a large-scale barotropic zonation, accompanied by an ensemble of barotropic vortical structures, many of which propagate zonally, at least qualitatively, like Rossby waves. The formation of the zonation in azimuthal flow appears to be largely as a result of direct eddy-zonal flow interactions, with a clear tendency for kinetic energy to accumulate upscale into the form of zonally-elongated structures or jets. Such a tendency is at least consistent with the hypothesis of Balk (2005) that such zonally-elongated structures will be favoured in flows constrained simultaneously to conserve the three dynamical invariants, energy, enstrophy and the geometric invariant noted by Balk (1991) for Rossby wave systems. It would be of interest in further work to investigate further the latter invariant in actual diagnostics of actual flows and numerical simulations, to examine in greater depth the validity of this hypothesis.

The scale favoured by the zonation process is a significant factor in determining the effect of zonostrophic anisotropy on flow structure. The Rhines wavenumber, k_R (as define in Eq (17)) has often been suggested as representing the likely scale of zonal jet formation. As originally noted by Hide (1966), such a scale represents a rough balance between relative and planetary vorticity advection, though this may not be the most useful balance to consider. Galperin et al. (2001) put forward an alternative interpretation, relating the favoured jet scale, represented by k_{fr} , to a balance between upscale energy transfer and large-scale energy removal. Both of these are effectively internal parameters, dependent on flow-dependent quantities, so are not particularly useful as predictive quantities. But they appear to be broadly consistent with the observed scale of jets found in the present experiments. However, our experiments II and III indicate in this case that $k_{fr} \simeq 1.5k_R$, which is not quite as suggested by Galperin et al. (2001) and Galperin et al. (2006) for the zonostrophic regime,

Table 2: Derived parameters for the three main experiments I - III. All wavenumber scales shown are in units of rad m^{-1} - see text for explanation of symbols.

Run	Ro^*	ϵ ($\text{m}^2 \text{s}^{-3}$)	k_ξ	k_β	k_{fr}	k_R	k_d	k_{dext}
I	2.2×10^{-3}	1.5×10^{-9}	49	2.1	< 3	1.4	> 13	0.13
II	1.3×10^{-2}	1.1×10^{-8}	20	5.2	~ 3	2.3	> 6.5	0.08
III	3.4×10^{-3}	6.6×10^{-9}	61	9.5	~ 6	4.9	> 13	0.16

though is close to the form suggested by Sukoriansky et al. (2007). In both cases II and III the scale k_{fr} corresponds quite closely to the radial wavenumber of the observed zonal jets, indicating that the scale separating adjacent zonal jets is reasonably well estimated by $\sim 1.5k_R$. The Rhines scale k_R also seems to be quite closely consistent with observed flows in the outer planets (e.g. Vasavada and Showman (2005)) and the oceans (Richards et al. 2006), which satisfy Eq (15) even more closely.

An important aspect of the near-equivalence of k_{fr} with k_R , asserted by Galperin et al. (2001), Galperin et al. (2006) and Sukoriansky et al. (2007), is the assumption that energy removal takes place in a relatively scale-independent manner. This is consistent, for example, with Ekman damping, such as would apply to our present experiments, and in the Earth’s oceans. The principal mechanism for energy removal on large scales on the gas giant planets, however, is not clear at the present time. None of the gas giants is believed to possess a solid underlying surface, so the relevance of Ekman damping seems unlikely. But presumably there must be some means of removing barotropic kinetic energy from the flow on large scales which, given the apparent consistency of the observed jets with the Rhines wavenumber, must act comparably on all scales. This is an aspect of the energy flow within the atmospheric circulation of these planets which deserves closer attention in future work.

7c. Convective forcing

The method of forcing used herein seems to work well as a ‘natural’ means of injecting energy at small scales, though the use of salt-driven convection does pose significant practical difficulties in sustaining a uniform and steady input of energy over long periods of time. In future experiments, it would be useful to explore the possibility of driving convection via imposed thermal contrasts, although providing sufficient heating and cooling (on the order of $10\text{-}100 \text{ W m}^{-2}$ on the scale of the Coriolis facility) would be a major undertaking. The imposition of unstable stratification has clear parallels with what may be happening in the atmospheres of the gas giant planets, though in their case the role of moist convective processes needs to be taken into account (Gierasch et al. 2000; Ingersoll et al. 2000). The lat-

ter probably concentrates intense convection into small and highly intermittent regions, though would certainly operate on a small scale compared with that of the planet itself. But an overall upwelling energy input of around $5\text{-}6 \text{ W m}^{-2}$ from the interior heat source on Jupiter (e.g. Vasavada and Showman (2005)), coupled with a depth for convection of at least 50 km, would suggest an average natural Rossby number Ro^* of 0.1 or less, placing it in a qualitatively similar convective regime to the present experiments.

Similar types of deep, rotationally-controlled convective forcing may also occur in the oceans (Marshall and Schott 1999), though only in very restricted regions such as the polar oceans and the Mediterranean. More commonly, it is baroclinic instability on horizontal scales of 50-100 km which provides the dominant source of ‘stirring’ in the wider ocean basins, and may be responsible for the energy input for the putative small-scale zonal jets now being found in ocean models and observations (Galperin et al. 2004; Maximenko et al. 2005; Richards et al. 2006). This was the original concept for exciting geostrophic turbulence by Salmon (1980), and there is certainly some evidence for zonation in small scale laboratory experiments on baroclinic instability using sloping endwalls (Mason 1975; Bastin and Read 1998), which would support the notion that the zonal-trophic regime does not depend strongly on the mechanism of small-scale energy injection. But laboratory experiments to date on baroclinic instability with sloping endwalls have been carried out only on a relatively small scale, and almost certainly have not satisfied the criteria expressed in Eq (15) above. It would be of significant interest to investigate this further on the scale of the Coriolis facility.

7d. Potential vorticity

The potential vorticity structure of the equilibrated banded zonal flow shows some clear signatures of intense interactions with eddies. Although the net effect of such interactions is to accelerate the zonal flow and to modify its structure, especially in the vicinity of Rossby critical layers which develop spontaneously as the flow evolves, the resulting instantaneous zonal flow ends up in a state which violates many of the ‘classical’ criteria for stability. Instantaneous velocity fields show evidence for smoothing out and even reversals of the radial

PV gradient, indicative of local Rossby wave breaking. Longer time-averages, however, are much closer to a state of neutral stability. This would seem to suggest that barotropic instability acts as an adjustment mechanism on long enough timescales in these experiments, such that instantaneous flows are indeed unstable but adjust the PV distribution over timescales of a few hundred τ_r towards marginal stability. This would appear to be in contrast to results from unforced numerical model simulations, which seem to produce jets which are much closer to neutral stability, even for instantaneous fields. The continuous forcing must therefore play a major role in perturbing the zonal flow away from this marginal state, by an amount which presumably depends on the strength of forcing.

It has long been noted that the westward zonal jets on the outer planets tend to violate the classical Rayleigh-Kuo/Charney-Stern instability criteria (Vasavada and Showman 2005; Read et al. 2006) (though may be closer to neutrality with respect to Arnold's second stability theorem (Dowling 1993, 1995)). This may again be a signature of the effect of the processes forcing the jets on Jupiter and Saturn, whose origins are still poorly understood in detail, though may lead to Rossby wave breaking as energy cascades upscale from the smaller-scale convective forcing. Further studies of the relationship between eddy forcing and stability criteria in experiments and models may be a useful source of further information on these mechanisms for driving zonal flows on the outer planets. Finally, we remark that the extent to which the small-scale jets found in ocean observations and models violate the classical instability criteria has not yet been investigated in detail, but could form an important means of discriminating between zonal-trophic mechanisms for jet formation and alternative mechanisms (e.g. see Berloff (2005)).

Acknowledgement We are grateful to the HYDRALAB program, funded by the EC contract *Access to Major Research Infrastructures*, for their support during the experimental design and acquisition phase of this project. Additional support was provided by the UK Particle Physics and Astronomy Research Council. Thanks are also due to the technical team at LEGI/Coriolis for their excellent assistance with the design and execution of the experiments, and to Profs B. Galperin and S. B. Sukoriansky for comments and discussions during the course of this study.
